

Figure 2e-h — the coordinate nulls audited: the published torus shift left the tissue, and the in-tissue replacements do not change the result

six Test-3-admissible sections, sender call tierA_p95; e-f are medians over sections, 20 draws each; g is over the 153 reportable fits, 1,000 permutations. N3-var / N4-var are the FROZEN PRIMARY null (green).

red = the published bounding-box nulls; green = the frozen primary variance-corrected null; $\hat{\lambda}$ is quoted with its IQR and railing rate, never alone

e Does the null leave the tissue?

f Does the null move anything?

N3-occ and N4-occ move senders barely further than $\hat{\lambda}$.
They are in tissue because they are near-identity, not because they are corrected.

g Old vs new surviving fraction

N3-swap $\equiv$ N1 — it destroys sender clustering, so it is NOT a corrected torus shift.

h Negative-control-probe kernel — M1 DONE, H1 pending

published bounding box in tissue degenerate equals N1 PRIMARY (variance-corrected)
